SAIFA QUANT EDGE 1.0

Risk Across Tails and Timescales

A wavelet-copula framework for horizon-aware portfolio risk

Research question: Does tail dependence change with the investment horizon, and what does ignoring this do to a portfolio's measured risk?

ROUND 1 - INITIAL SCREENING CHALLENGE

Reproducible analysis | 7 October 2026

Executive answer

Yes. Average empirical lower-tail co-exceedance ranges from 0.28 to 0.33 across wavelet horizons. At the largest risk-measurement difference (8-16 days), horizon-specific modelling produces 99% Expected Shortfall that is 8.3% higher than the single-dependence benchmark.

Decision

A risk manager should match the dependence model to the holding horizon. For exposures dominated by the 8-16 days band, replace the fixed Gaussian dependence assumption with the fitted horizon-specific Student-t copula and set the component ES budget to 0.933% of portfolio value at 99% confidence. Re-estimate after material market-regime changes.

What was tested

An equal-weight portfolio of 4 public market proxies was studied from 2016-10-07 to 2026-10-06. The first 80% of returns formed the estimation sample (ending 2024-10-03); the remaining 20% formed an untouched holdout sample (starting 2024-10-04). The mean absolute gap between the observed VaR exception rate and the nominal 1% rate is 0.45 percentage points for the wavelet-t model and 0.45 for the benchmark; by this coverage diagnostic, the Gaussian benchmark is closer on average.

Contribution

The comparison holds each wavelet band's empirical marginal distributions fixed. Only the dependence model changes: a Student-t copula estimated separately at each horizon versus one Gaussian copula estimated from raw daily returns and reused everywhere. The resulting ES difference is therefore attributable to dependence and tail assumptions rather than volatility scaling.

1. Portfolio and experimental design

The portfolio intentionally mixes two correlated equity indices with commodity and currency exposures. Equal weights avoid optimizing on the same sample used to test risk, and all inputs are public, daily, and reproducible without an API key.

Series	Economic exposure	Weight	Reason for inclusion
SP500	Large-cap US equity	25%	Broad equity-market loss factor
NASDAQCOM	Technology-heavy US equity	25%	Concentrated growth exposure
DCOILBRENTEU	Brent spot crude oil	25%	Commodity and inflation shock factor
DEXUSEU	Long EUR / short USD	25%	Major liquid currency exposure

Choice	Specification	Rationale
Return	Daily log change	Additive through time; comparable across level series
Wavelet	Haar maximum-overlap/SWT, 4 levels	Additive, shift-invariant bands with transparent horizons
Main dependence	Student-t copula by band	Allows symmetric asymptotic tail dependence
Benchmark	One Gaussian copula from raw returns	Simple model with no asymptotic tail dependence
Risk	99% VaR and Expected Shortfall	VaR is backtestable; ES measures severity beyond VaR
Validation	Chronological 80/20 holdout	Prevents fitting dependence to the evaluation period

Data are aligned to a common business-day index; isolated publication gaps of at most 5 days are carried forward before log returns are calculated. This treats the index levels as tradable exposure proxies rather than claiming exact ETF implementation.

2. Method

Wavelet decomposition

For each asset return series r(t), the stationary wavelet transform produces additive components r(t) = A4(t) + D4(t) + D3(t) + D2(t) + D1(t). The detail bands correspond approximately to 16-32 days, 8-16 days, 4-8 days, 2-4 days trading-day oscillations; A4 captures variation >32 days. The transform is applied separately to estimation and holdout samples.

Copula estimation

Within each band, ranks are converted to pseudo-observations. For each candidate degrees-of-freedom value, pseudo-observations are mapped through the Student-t quantile, a correlation matrix is estimated, and the copula log-likelihood is evaluated. Bounded maximum likelihood selects degrees of freedom between 2.05 and 50. The benchmark maps raw-return ranks through the normal quantile once and reuses that correlation matrix at every horizon.

Risk simulation

Each model generates 100,000 joint uniform draws. Inverse empirical marginal distributions convert these draws back to band-specific asset returns. Portfolio losses use the configured weights. VaR is the 99th percentile of loss and ES is the mean loss conditional on exceeding VaR.

Out-of-sample test

Model parameters and risk thresholds are frozen after estimation. Holdout wavelet-band portfolio losses are compared with each model's VaR. We report the exception rate and quantile loss; at a 99% VaR level, ideal coverage is approximately 1%. This is a distributional holdout test, not a rolling one-day trading forecast.

Identification

Because both models use the same band-specific empirical margins, changes in measured risk isolate the consequence of replacing horizon-specific heavy-tailed dependence with one Gaussian dependence structure. This controlled comparison directly answers the challenge question.

3. Tail dependence changes with horizon

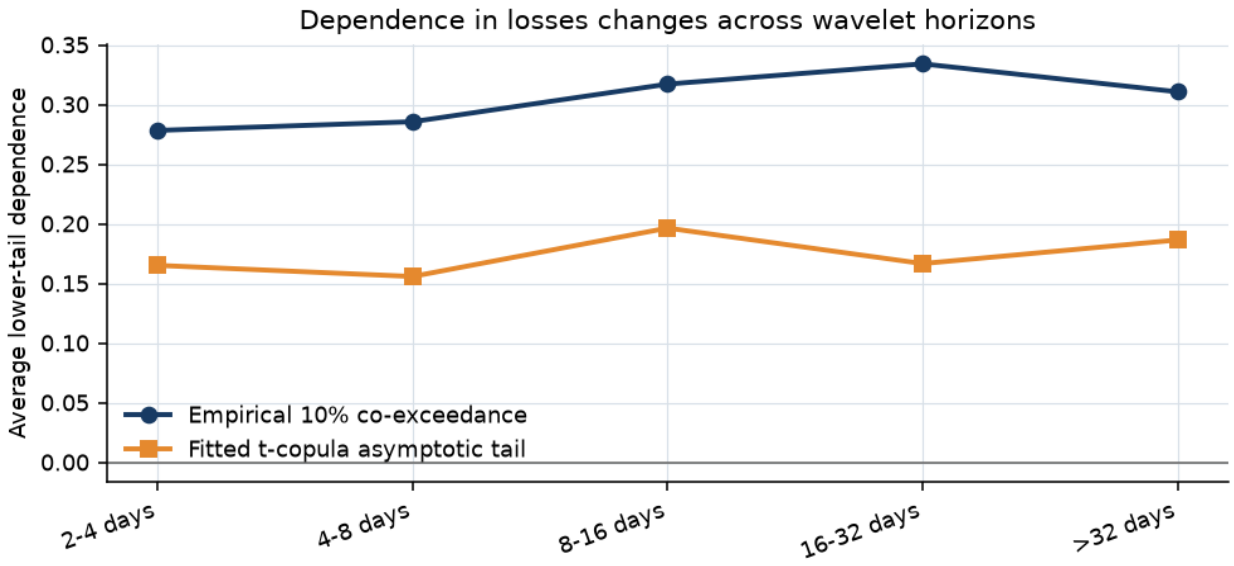

Figure 1. Average across the 6 asset pairs. Empirical co-exceedance is P(Uj <= 0.10 | Ui <= 0.10); t-copula tail dependence is the fitted asymptotic coefficient.

Horizon	Empirical co-exceed.	t-copula tail	t df	Mean correlation
2-4 days	0.278	0.165	5.59	0.245
4-8 days	0.286	0.156	5.70	0.253
8-16 days	0.317	0.196	5.08	0.346
16-32 days	0.334	0.167	6.60	0.374
>32 days	0.311	0.187	5.00	0.322

The non-flat profile is inconsistent with the practical assumption that one dependence structure adequately represents every holding horizon. The fitted degrees of freedom also change by band, indicating that joint-tail thickness is not constant even when the asset set and sample are unchanged.

4. Effect on measured portfolio risk

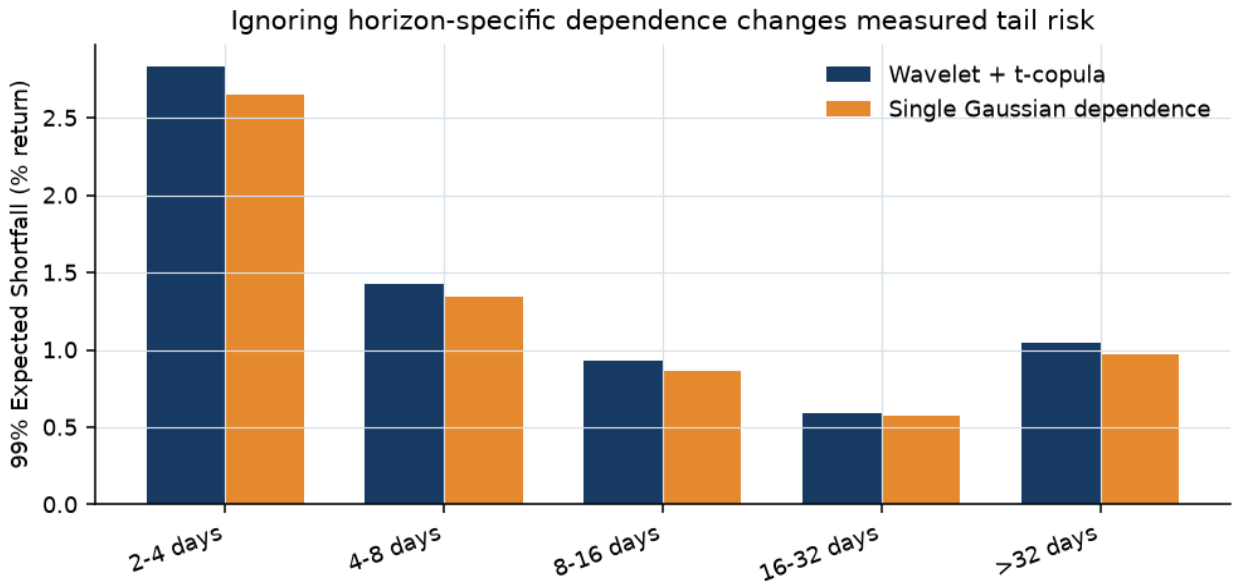

Figure 2. Simulated 99% Expected Shortfall for each additive return band. Margins are identical across models; dependence assumptions differ.

Horizon	t VaR	t ES	Gaussian VaR	Gaussian ES	ES change
2-4 days	1.792%	2.834%	1.753%	2.651%	+6.9%
4-8 days	0.876%	1.426%	0.847%	1.344%	+6.1%
8-16 days	0.600%	0.933%	0.557%	0.861%	+8.3%
16-32 days	0.389%	0.588%	0.378%	0.570%	+3.0%
>32 days	0.740%	1.046%	0.710%	0.970%	+7.8%

A positive ES change means the single Gaussian structure understates loss severity relative to the horizon-specific Student-t model; a negative value means it overstates it. The direction need not be identical at every scale, which is exactly why a single adjustment factor is insufficient.

5. Out-of-sample comparison

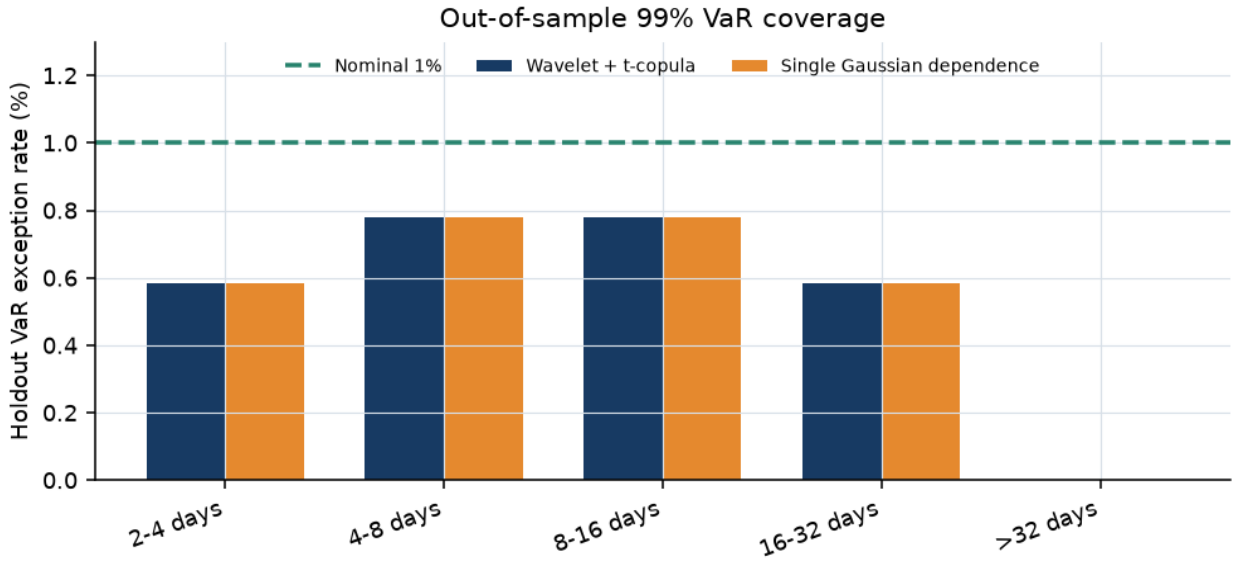

Figure 3. Holdout VaR exception rates. The dashed line is the nominal 1% rate; small holdout samples make exact equality unlikely.

Horizon	N	t exceptions	t rate	Gaussian exceptions	Gaussian rate	Better q-loss
2-4 days	512	3	0.59%	3	0.59%	Gaussian
4-8 days	512	4	0.78%	4	0.78%	Gaussian
8-16 days	512	4	0.78%	4	0.78%	Gaussian
16-32 days	512	3	0.59%	3	0.59%	Gaussian
>32 days	512	0	0.00%	0	0.00%	Gaussian

Coverage and quantile loss are complementary. Coverage asks whether the threshold is crossed at the intended frequency; quantile loss also penalizes how far observations fall on either side of the threshold. The holdout test prevents a more flexible t-copula from receiving credit merely for fitting its training sample.

6. Recommendation, limits and robustness

Action for tomorrow: map each risk position to its holding horizon and use that band's fitted t-copula ES. For the 8-16 days component, budget 0.933% of portfolio value at 99% ES rather than 0.861% from the fixed Gaussian model (+8.3% difference).

Implementation rule

Maintain the existing Gaussian result as a challenger, not as the production number. Refit horizon models on a scheduled basis and trigger an unscheduled review when realized VaR exceptions cluster. Escalate when the horizon-specific ES exceeds the Gaussian ES by the institution's materiality threshold.

Limitations

Limitation	Consequence and next test
Index/spot proxies	Implementation costs, futures rolls and ETF tracking are absent; repeat with investable instruments.
Fixed 80/20 split	One market regime can dominate; add rolling-window and crisis-subperiod validation.
Symmetric t tails	Upside and downside dependence share one parameter; compare with Clayton, Gumbel or vine copulas.
Wavelet boundary effects	Edge coefficients are affected by periodic extension; test longer samples and alternative filters.
Band-level risk	Results describe additive horizon components, not a fully dynamic multi-period P&L forecast.
Empirical margins	Extreme quantiles rely on finite samples; compare generalized Pareto tail models.

Robust interpretation

The defensible result is the existence and economic size of horizon variation within this sample. The framework should not be read as proof that one copula family will dominate for every portfolio or future regime.

7. Reproducibility, AI disclosure and references

Reproduction

From the project root run: `uv run python run.py`. This one command recreates all tables, figures, machine-readable results and this PDF. The included data snapshot fixes the submitted result; the refresh option retrieves current FRED observations. Random generation uses the seed recorded in the central configuration and model-parameter output. Refresh flag: `--refresh-data`.

Material use of AI tools

OpenAI Codex was used for research design discussion, Python implementation, debugging, report drafting and formatting. The team remains responsible for checking every method, line of code, result and statement. No result in this report is accepted solely because an AI tool produced it; all reported numbers are generated by the submitted code and public data.
